First Draft

Abstract

This paper introduces **Emergence Dynamics**, a novel computational paradigm in which computation is represented as **Emergence**: a process of **Evolutionary Nondeterministic State Transitions** over dynamically evolving **Markets**, driven by interactions among **Agents** whose **Beliefs** and **Measure Spaces** evolve in response to **Information** to price an **Event**. I mathematically formalize those concepts and prove that Turing machines can be embedded as a degenerate special case under the emergence dynamics paradigm. I further develop a **Geometric Perspective on P versus NP** and computational complexity by mapping 3-SAT into the emergence dynamics framework. This construction motivates conjectures on exponential resource–time duality, computational spacetime-volume, and inverse reconstruction. My conjectures do not constitute a proof of $P \neq NP$, but define a research program for investigating whether computational hardness can be characterized through **Entropy**, **Flow**, **Singularities**, **Computational Surgery**, and other geometric obstructions to computation.

The paradigm is first applied to financial markets—I examine the **Boundaries of the Efficient Market Hypothesis** and the Black-Scholes model. I introduce the concept of **Cross-Measure Arbitrage**, a market mechanism arising from inconsistencies among dynamically evolving agent beliefs and pricing measure spaces. I further develop a general architecture for **Perpetual Derivatives**, including **Event Contracts** and **Trustless Insurance**. Besides, the paradigm might further inspire studies on AGI, hallucination, embodied AI, and beyond.

Keywords: Emergence Dynamics, Continuous Measurement, Nondeterministic State Flows, Computation as Emergence, Computational Complexity, Geometrization of P versus NP , 3-SAT, Embedding of Turing Machines, Event Contract, Trustless Insurance, Perpetual Derivatives, AGI

Important Notes

I have realized that the chronological genesis of an idea carries deeper scientific value than the paper itself. Therefore, I have open-sourced all intermediary materials, including conversations (human prompts and AI responses), draft papers, images, corpora, and other materials, to serve as a rigorous empirical case study for future investigations in cognitive science, psychology, and the heuristics of scientific discovery. Visit <https://github.com/theparadigmgroup/EmergenceDynamics> to download these materials.

I encourage all researchers to open-source their prompts and streams of research ideas and thoughts, rather than only their final papers. The non-linear thought process is far more critical than the publication itself. In fact, some of those abandoned, mid-way discarded ideas (much like the “scratch papers” of Gauss or Newton) hold infinitely more value than the papers themselves, even if the authors fail to realize their importance at the time—largely because the true significance of these raw ideas often manifests in entirely unpredictable, seemingly unrelated fields.

Therefore, I urge the scientific community to develop platforms dedicated exclusively to open-sourcing streams of research ideas and thoughts—a conceptual equivalent to arXiv—which would also serve as a powerful deterrent against academic fraud. Modern papers, in an effort to appease peer reviewers (often rigid “experts” who excel merely at standard linear thinking), are forced to strip away the living, breathing reality of exploration—the dead ends, the walls hit, and the non-linear intuitions—and artificially package them into a cold, smooth, linear chain of causality. A paper is a “results-oriented” specimen. Conversely, a platform dedicated to open-sourcing streams of research ideas and thoughts aims to preserve, in their authentic and raw form, those genius *Eureka!* moments in the minds of “Prometheus”.

1 Introduction: The Mom’s Phone Call Market — An Intuitive Thought Experiment on Why We Can’t Ever Fully Understand Each Other

Before we dive into the rigorous mathematical formalisms of continuous measure spaces and nondeterministic state flows, let us pause for a simple, human question: *Are you by your mom’s side right now? If not, when was the last time you called her?* Do you truly understand her persistent nagging, or does she look past your impatience to grasp your silent anxieties? While we all long for a mom who is always on our side, comprehends and loves us unconditionally, pure epistemological alignment between two independent minds remains an absolute mathematical impossibility.

Let us imagine every phone call with my mom as a dynamic pricing game—or more intuitively, a **Market** between two **Agents**, my mom and me—pricing an emerging **Event**. We bid our prices under entirely distinct, evolving **Measure Spaces** with subjective **Belief Functions** over incoming **Information Flow**. As the conversation unfolds, the **State** transitions—information flows in, belief functions shift, and even the underlying measure spaces drift...

Consider a concrete binary event: *I have fallen in love with some Nondeterministic girl, say, Eve, and I am calling my mom to ask for her approval while simultaneously trying to price this very outcome.* This dramatic pricing game usually crashes into one of four glorious landings: the double green light where we both agree SHE IS THE ONE; the classic showdown where I’m head over heels, while my mom is waving giant red flags, and I’m ready to sign the lease anyway; the mutual surrender where we both eventually sigh and agree it was a bad idea; or, the FUNNIEST of all, the pure plot twist where my mom falls completely in love with her, insists she’s an angel sent by God, while I’m left sitting there suddenly having second thoughts about the whole thing.

Now, let us look at the underlying measures we bring to this pricing game. My mom holds exactly one eternal measure, and it is absolute and immutable: *“Mom love you forever!”* I, on the other hand, enter the phone call juggling two distinctively dramatic measures. Before the call even begins, my active measure is: *“Eve is an extraordinary, wonderful girl!”* But lurking beneath it is my fallback, bare-minimum measure: *“Well, Eve is at least a girl...”*

When this dynamic mini market between my mom and me refuses to immediately **Collapse** into a discrete terminal state with observed price $P = 0$ or $P = 1$, remaining stuck in a continuous, uncollapsed superposition $P_{\text{nondeterminism}}$, we witness what I define as **Emergence**. Specifically, *emergence is not the collapse of the market; rather, it is the ongoing, uncollapsed generative process that precedes it.* Collapse is a form of observation—it represents the rigid assignment of a label, the liquidation of a trade, or the termination of a conversation. Emergence, by contrast, is the dynamic pricing game of the market itself: the **Unexplainable**, non-deterministic state transitions born as agents continuously update their unobservable belief functions across evolving measure spaces under the incoming information flow. Where, then, does **Necessity** reside in this emergence dynamics? Necessity is in the invariant anchoring measures and boundary conditions that constrain the market. Just like my mom’s irreducible baseline measure—*“Mom love you forever!”*.

However, because neither the information flow, measure spaces, nor internal belief functions are directly observable or intrinsically explainable, what remains observable is merely the agreement or collision itself. I frequently find myself arguing with my mom; yet, amid the emotional noise of every conflict, she inevitably offers three fundamental responses:

1. *“Mom don’t understand.”*—a candid admission that under her current measure space, there exists no or weak subjective belief functions capable of projecting the incoming information flow.

2. “*Mom will learn.*”—a dynamic, continuous update of her measure space and subjective belief functions for projecting the incoming information flow.
3. And ultimately, “*Mom love you forever!*”—an unexplainable baseline measure, an anchor of absolute necessity.

Let us pause here and ask ourselves a fundamental question: How do we measure my mom’s unconditional love? Should we tag static, discrete labels to a continuous information flow?

Consider the lineage of our ancestors. When my mom was a little girl, she also argued with my grandma and got educated, usually receiving static, discrete labels of “ground truth” data. Over time, her mind continuously constructed and expanded its measure space and belief functions *ex nihilo*—creating new dimensions of understanding out of thin air to accommodate the unexplainable. In turn, she applied those learned labels, measures, and belief functions to teach me. If we merely build Artificial General Intelligence (AGI) by feeding AGI with static pre-labeled datasets, are we not simply hardcoding a historical recursion of observed collapses?

Let us further trace this back to the absolute origin: when my mom was merely a fertilized egg or embryo, did any of those explicit belief functions, labeled data, or measures exist a priori? Absolutely not. They emerge dynamically, much like evolutionism or the evolutionary progression of science itself. Consider this: if we had permanently tagged Aristotle with an immutable label of “absolute ground truth”, how could Newton ever have laid the foundations of classical mechanics? And if we had dogmatically labeled Newtonian physics as the immutable “absolute ground truth”, how could Einstein have rewritten our universe with relativity?

Therefore, the paradigm of **Emergence Dynamics**—grounded in evolving non-deterministic state flows, measure spaces, belief functions, and agent pricing games under unlabeled information flow—presents a radical redefinition of **Computation** itself. It pronounces a silent death sentence on traditional Turing machines and today’s statically trained Large Language Models. My ultimate objective in this work is to redefine computation as an evolutionary emergence—a continuous, non-deterministic state flow where intelligence continuously expands its measure spaces and belief functions *ex nihilo*, pricing an unexplainable universe long before any observation forces it to collapse.

2 Formalizing the Market with Mathematical Definitions

2.1 Core Concepts: State, Information, Event, Agent, Belief, and Measure

To strip away human bias and examine the paradigm of continuous measurement and nondeterministic state flows in its purest form, let us imagine the **United Sloths of Mars (USM)**—a civilization operating at a glacial velocity whose economy runs on the **United Sloths Dollar (USD)**. At the center of this low-frequency market sits **MacroSoft (MAFT)**, a software titan founded by the visionary sloth entrepreneur Tab Doors. Today, MAFT stands as an undisputed heavyweight of the Martian **Sloths & Patience 500 (SP500)** index. Because a single strategic shift by Tab Doors unfolds over months—*please understand that we are talking about sloths...*—pricing MacroSoft is never a quickly observed price collapse, but an evolving, non-deterministic dynamic pricing game: a living superposition where raw information trickles in, and each sloth agent’s subjective belief function and measure space slowly evolve over time.

Consider a tail-risk hedging **Event Contract** C_E . Let $S_t := S(s_t)$ denote the stochastic spot price process of MAFT on $(\Omega, \mathcal{F})$ —where Ω represents the underlying space of all possible market sample paths and $\mathcal{F}$ is the σ -algebra of measurable path events—with an initial spot price $S_0 = 500$ USD. Agents seek to price a binary event E , which represents the tail-risk event where

the spot price of MAFT drops below 400 USD at any point over time. The final settlement of the event contract C_E is governed by an external **Oracle** $\mathcal{O}$. Define the first-passage time to breach the tail-risk spot price threshold as:

$$\tau_E(\omega) := \inf\{t \geq 0 : S_t(\omega) < 400\}, \quad \inf \emptyset := \infty$$

Define the tail event:

$$E := \{\omega \in \Omega : \tau_E(\omega) < \infty\} \in \mathcal{F}$$

Let:

$$\tau_{\mathcal{O}} := \inf\{t \geq 0 : \mathcal{O} \text{ verifies that } \tau_E \leq t\}$$

At any time t , the price of the event contract $P_t(C_E)$ is given by:

$$P_t(C_E) = \begin{cases} 1 \text{ USD}, & t \geq \tau_{\mathcal{O}}, \\ \tilde{P}_t(C_E), & t < \tau_{\mathcal{O}}, \end{cases} \quad \tilde{P}_t(C_E) \in [0, 1] \text{ USD} \quad (1)$$

As long as MAFT never breaches below 400 USD, $\mathcal{O}$ stays silent. The event contract never settles, leaving agents to perpetually price $P_t(C_E) \in [0, 1]$ through incoming information flow, subjective belief functions, and continuous measure space evolutions.

Under classical quantitative finance, such as the Black-Scholes-Merton (BSM) model [1, 7], the pricing of a financial derivative explicitly presupposes the existence of a globally shared risk-neutral measure $\mathbb{Q}$. However, under our paradigm, such a global measure $\mathbb{Q}_{\mathcal{O}}$ exists strictly as a localized property of the external oracle $\mathcal{O}$. Prior to the oracle's final settlement, each sloth agent $a_i \in \mathcal{A}$ processes incoming information flow through an evolving subjective belief function that projects the contract price onto a likewise evolving subjective measure space $\mathbb{Q}_t^{(i)}$.

Let us formalize core market concepts:

Definition 2.1 (Raw Information Filtration). The **Raw Information Filtration** is $\mathbb{I} = \{\mathcal{I}_t\}_{t \geq 0}$, where each $\mathcal{I}_t$ is a sub- σ -algebra of $\mathcal{F}$ and $\mathcal{I}_s \subseteq \mathcal{I}_t \subseteq \mathcal{F}$ for all $0 \leq s \leq t$. It represents the information revealed by time t .

Definition 2.2 (State and Nondeterministic State Transition). Let $(\Omega, \mathcal{F}, \{\mathcal{I}_t\}_{t \geq 0})$ denote the underlying filtered measurable sample path space, and let X denote the space of admissible market configurations. For a realized sample path $\omega \in \Omega$, a **State** at time t is an instantaneous configuration:

$$X_t(\omega) = \left(M_t, I_t, \{B_t^{(i)}, \mathbb{Q}_t^{(i)}\}_{i \in \mathcal{A}_t}, O_t \right) \in X$$

Where M_t represents the observable market configuration, I_t represents the observed information history associated with $\mathcal{I}_t$, $B_t^{(i)}$ and $\mathbb{Q}_t^{(i)}$ represent agent i 's current subjective belief function and measure, and O_t represents the oracle and settlement status.

Let $0 \leq \tau_1 < \tau_2 < \dots$ denote the discrete update. A **Nondeterministic State Transition** is an update:

$$X_{\tau_k^-}(\omega) \longrightarrow X_{\tau_k}(\omega)$$

During which one or more components of the market state may change. Such an update may be induced by new information, an agent's drift in belief or measure, or an oracle settlement. The

transition is nondeterministic if the same pre-transition state may transit to multiple possible post-transition states.

Definition 2.3 (Event). An **Event** $E \in \mathcal{F}$ is a measurable subset of the sample path space Ω , representing a well-defined proposition or path-dependent condition on the underlying market-state trajectories.

Definition 2.4 (Agent, Belief, and Measure). An **Agent** $a_i \in A_t$ is an active market pricing entity indexed by i , characterized by:

1. An **Evolving Subjective Belief Operator**:

$B_t^{(i)} : I_t^{(i)} \rightarrow \mathcal{P}(\Omega, \mathcal{F})$, which maps the information history $I_t^{(i)}$ observable by agent a_i at time t to a subjective probability measure over the sample path space.

2. An **Evolving Subjective Measure**:

$\mathbb{Q}_t^{(i)} = B_t^{(i)}(I_t^{(i)}) \in \mathcal{P}(\Omega, \mathcal{F})$, representing agent a_i 's localized probability measure over path events $E \in \mathcal{F}$ given the agent's observable information history $I_t^{(i)}$ at time t .

2.2 The Price Emergence Formula

Let $\mathcal{F}_t := \mathcal{I}_t$ denote the market information filtration at time t . Assume that a measure-aggregation operator Agg_t is given and define:

$$\mathbb{Q}_t := Agg_t \left(\{\mathbb{Q}_t^{(i)}\}_{i \in A_t} \right) \in \mathcal{P}(\Omega, \mathcal{F})$$

Let $\Psi : \Omega \rightarrow \mathbb{R}$ denote a measurable target payoff or path-dependent quantity, for every relevant t , Ψ satisfies:

$$\Psi \in L^2(\Omega, \mathcal{F}, \mathbb{Q}_t)$$

For each t , define its conditional projection by:

$$\Pi_{\mathbb{Q}_t}(\Psi \mid \mathcal{F}_t) := \arg \min_{Z \in L^2(\Omega, \mathcal{F}_t, \mathbb{Q}_t)} \mathbb{E}_{\mathbb{Q}_t} [(\Psi - Z)^2]$$

The **Price Emergence Formula** is then postulated as

$$\boxed{P_t := \Pi_{\mathbb{Q}_t}(\Psi \mid \mathcal{F}_t) = \mathbb{E}_{\mathbb{Q}_t} [\Psi \mid \mathcal{F}_t]} \quad (2)$$

Thus, the emergent price P_t is the best $\mathcal{F}_t$ -measurable mean-square projection of the target payoff Ψ under the aggregated measure $\mathbb{Q}_t$.

2.3 Intuition behind Market Collapse and Emergence: Copernicus, Columbus, Newton, Morgan, and Bose

To intuitively understand the dynamics behind market collapse and emergence, let us consider a simple thought experiment. Suppose a multitude of subjective markets $\mathcal{M} = \{M_1, M_2, \dots\}$ are concurrently pricing an underlying target event E . Prior to external dynamics, each market M_k operates under a localized subjective measure $\mathbb{Q}_t^{(k)}$, while its associated contract remains unsettled through a sequence of nondeterministic state transitions.

Now, let us consider a stream of raw, uncured information flow entering the market network—for instance, an “apparently irrelevant” exogenous piece of information, such as a famous celebrity sloth on Mars getting married. Classical finance would discard such information as pure noise. However, under our paradigm, the **Intrinsic Importance** of a new information item ξ_t is heuristically measured by its **Collapsing Capacity**: the proportion of markets it causes to abruptly collapse into terminal prices $P_{\tau_t}^{(k)} \in \{0, 1\}$.

When the important information triggers a rapid collapse in a small subset of markets while the broader majority remains in unsettled superposition and nondeterministic state transitions, I designate these early-collapsing markets as **Heretical Markets**. These heretical markets are not anomalies to be filtered; they represent early phase transitions in localized measure spaces. Let us discuss a few important heresies in the history of science.

1. **Copernicus’s Heliocentrism Paradigm Shift [4]**: Long before the world widely accepted heliocentrism, Copernicus had already changed the minds of a few astronomers.
2. **Columbus’s Route Discovery to “India” [3]**: What started as a search for India collapsed into the discovery of the Americas, a fundamental change in his frame of reference (measure).
3. **Newton’s Apple [9]**: The simple observation of a falling apple acted as a high-capacity collapsing piece of information.
4. **Morgan’s Fruit Flies [8]**: A single mutant white-eyed *Drosophila* in a lab collapsed Morgan’s localized genetic inheritance market, giving birth to the chromosome theory.
5. **Bose’s Non-Classical Statistics [2]**: The non-classical counting of indistinguishable photons collapsed Bose’s localized belief, establishing Bose-Einstein condensation.

Therefore, detecting intrinsically important information is crucial, and observing early-stage heretical markets is also critical, because these heretical markets can detect information with high intrinsic importance which classical markets dismiss as noise. Emergence is not an instantaneous event, but a non-linear propagation process through which these heretical markets drift their localized beliefs and measure spaces and scale up to trigger a global phase transition.

2.4 The “Nonsensical” Event Coupling Effect under Cross-Market Entanglement

In classical econometric frameworks, event coupling is strictly bound by statistical correlation. If an event E_A (e.g., an “apparently irrelevant” social noise) shares no statistical relevance with another event E_B (e.g., MacroSoft enterprise cloud is down), traditional models enforce $\text{Cov}(E_A, E_B) \approx 0$.

In reality, though, sloth chaos defies statistics. Imagine a critical sloth site reliability engineer at MacroSoft is captivated by a celebrity scandal and he misses a crucial service down alert. This might ultimately trigger a massive cloud outage, thus two “apparently unrelated” events collide. However, under our paradigm, the global event market network forms a **Fibered Market System**:

$$\pi : \mathcal{E} \longrightarrow \mathcal{B}$$

Where $\mathcal{B}$ denotes the market-interaction space and each point $b \in \mathcal{B}$ identifies a local market M_b . The fiber $F_b := \pi^{-1}(b)$ contains the admissible market configurations of agents’ subjective beliefs and measures, pricing states, and nondeterministic transitions associated with M_b .

Consequently, a collapse in market M_a (triggered by an observation of event E_A) induces a nontrivial parallel transport across the total space E . Through the bundle’s gauge curvature,

this motion exerts a non-local impulse on market M_b , forcing an abrupt state transition in event E_B —even in the complete absence of classical statistical correlation.

Definition 2.5 (Cross-Measure Event Entanglement). Two semantically orthogonal events $E_A, E_B \in \mathcal{F}$ are **Cross-Measure Entangled** if the observation-induced collapse of localized subjective measure spaces $\mathbb{Q}_{s_t}^{(i)}(E_A)$ in market M_A induces a non-trivial parallel transport across the total space E , forcing an instantaneous reallocation of boundary capacity $C(\tau)$ or shifting of agent belief distributions, thereby triggering an abrupt, cascading collapse in E_B .

This mechanism introduces what I define as the “**Nonsensical**” **Event Coupling Effect**. It represents a dynamical instability far more unpredictable than Lorenz’s classic **Butterfly Effect** [6].

3 Why Hallucinations are Inevitable: A Key to Artificial General Intelligence

3.1 A Mathematical Definition of Cognitive Hallucination

Rather than localized token probability $P(y_t \mid y_{<t}, x)$, let us redefine an LLM output as an information-conditioned orthogonal projection of an unobservable latent semantic truth state $\Psi \in L^2(\Omega, \mathcal{F}, \mathbb{Q}_I)$ onto an expanding context filtration stream $\mathbb{F} = \{\mathcal{F}_t\}_{t \geq 0}$ under some information-neutral prior measure $\mathbb{Q}_I$. Let $(\Omega, \mathcal{F}, \mathbb{Q}_I)$ be the measurable probability space parameterized by static trained model weights W .

Definition 3.1 (LLM Output Operator and Cognitive Hallucination). The output of an LLM at time t , denoted as P_t , is the orthogonal projection:

$$P_t = \Pi_{\mathbb{Q}_I}(\Psi \mid \mathcal{F}_t) \equiv \mathbb{E}_{\mathbb{Q}_I}[\Psi \mid \mathcal{F}_t] \quad (3)$$

A **Cognitive Hallucination** is defined as the nonzero orthogonal projection error variance $\sigma_t^2 > 0$ under incomplete filtration $\mathcal{F}_t \neq \mathcal{F}$:

$$\sigma_t^2 = \mathbb{E}_{\mathbb{Q}_I}[(\Psi - P_t)^2 \mid \mathcal{F}_t] \quad (4)$$

3.2 The Inevitable Hallucination Theorem: A Mathematical Proof

Theorem 3.2 (Martingale Property and Monotonic Variance Reduction). *The stochastic sequence $\{P_t\}_{t \geq 0}$ forms a martingale with respect to $\mathbb{F}$ under $\mathbb{Q}_I$. Furthermore, expected error variance is strictly non-increasing over filtration expansion:*

$$\mathbb{E}_{\mathbb{Q}_I}[\sigma_s^2] = \mathbb{E}_{\mathbb{Q}_I}[\sigma_t^2] + \mathbb{E}_{\mathbb{Q}_I}[(P_t - P_s)^2] \implies \mathbb{E}_{\mathbb{Q}_I}[\sigma_s^2] \geq \mathbb{E}_{\mathbb{Q}_I}[\sigma_t^2] \quad (\forall s \leq t) \quad (5)$$

Proof. By the tower property, $\mathbb{E}_{\mathbb{Q}_I}[P_t \mid \mathcal{F}_s] = \mathbb{E}_{\mathbb{Q}_I}[\mathbb{E}_{\mathbb{Q}_I}[\Psi \mid \mathcal{F}_t] \mid \mathcal{F}_s] = P_s$. Applying the law of total variance yields the non-increasing property directly. $\square$

Corollary 3.3 (The Inevitable Hallucination Theorem). *For any non-degenerate state Ψ that is not $\mathcal{F}_t$ -measurable, expected hallucination variance is strictly bounded away from zero:*

$$\mathbb{E}_{\mathbb{Q}_I}[\sigma_t^2] > 0 \quad \forall \mathcal{F}_t \neq \mathcal{F} \quad (6)$$

Proof. By the Hilbert space projection theorem, the projection error $(\Psi - P_t)$ is orthogonal to $L^2(\Omega, \mathcal{F}_t, \mathbb{Q}_I)$. Since $\mathcal{F}_t \neq \mathcal{F}$, the norm $\|\Psi - P_t\|_2^2 > 0$ cannot vanish prior to complete information closure $\mathcal{F}_t \equiv \mathcal{F}$. $\square$

Thus, hallucination is an inescapable mathematical property of bounded informational systems. Managing projection variance—rather than attempting its elimination—is the true gateway to AGI.

3.3 The Stream of Consciousness Experiment

Prior to introducing the experiment I conducted in Section 3.3, it is necessary to address a foundational reality that every non-trivial software or computational framework contains bugs [10]. This absolute boundary of computer science is not merely an engineering shortcoming, but a fundamental property of computational complexity and state-space explosion. As Turing Award winner Edsger W. Dijkstra famously stated[5]:

“Program testing can be used to show the presence of bugs, but never to show their absence!”

Under our paradigm, a “bug” or a “hallucination” is mathematically equivalent—both represent localized failures of a closed filtration stream $\mathcal{F}_t$ to bound orthogonal projection errors against the unobservable global state space Ω . Since testing can only sample finite trajectories, no empirical validation can ever guarantee the absolute absence of uncollapsed projection anomalies.

However, the objective of emergence dynamics is not to dogmatically assert the impossibility of bugs, but to detect critical bugs in advance, identify their mechanics and boundary conditions, and fix them. The bug I show here—**has been formally identified, bounded, and resolved**.

To intuitively explain what is the **Stream of Consciousness Experiment**, I conducted a real-time subconscious behavioral tracing experiment within a commercial mobile travel app across a 22-minute time frame (from May 26, 2026, 23 : 52 to May 27, 2026, 00 : 14). I conducted my experiment under extreme real-world constraints and severe mental health overload at that time. My objective was to book a hotel in Manhattan and check out on May 27, 2026. I found these bugs:

1. **Filter Deadlock Loop:** The search got stuck in an infinite loop filtering for **Manhattan** $\rightarrow$ **Midtown** $\rightarrow$ **Hotel** $\rightarrow$ **Manhattan** $\rightarrow$... I force-collapsed the minimum price threshold up to \$977 just to break out of the infinite loop and trigger fresh listings.
2. **Maximum Price Cap:** The UI slider displayed a maximum price of \$1,000, even though the actual maximum property prices in the search results page were well over \$1,000.
3. **Asynchronous Check-in Misalignment:** After completing the booking past midnight, the app defaulted my check-in time to May 27 at 4:00 PM (16 hours later) instead of recognizing my immediate, same-night need.

Figure 1: **Empirical Execution Trace of the Stream of Consciousness Experiment.** My objective was to book a hotel in Manhattan (continued on next page)...

Figure 1: **Empirical Execution Trace of the Stream of Consciousness Experiment (Continued)**. And I found three bugs in this commercial mobile travel app.

Figure 2: **Another Empirical Execution Trace of the Stream of Consciousness Experiment**. This “another app” had some crazy bugs... Every vehicle would arrive in 1 min... Current time was 00:14, but the estimated arrival time was 00:20 (in 1 min???)...

Basically, like stream-of-consciousness writing, which lets your thoughts flow directly onto the page as they naturally happen—no filtering, no overthinking, and no worrying about any “ground truth” labels, the stream of consciousness experiment just captures the raw data “subconsciously” or “unconsciously”.

3.4 The “Martin Luther Jin” (MLJ) Test and the Heuristic Hallucination

The classical Turing Test, originally formulated by Alan Turing as some “Imitation Game”, evaluates artificial intelligence based on superficial textual outputs that lead a human interrogator to mistake the AI for a human [11]. Under the classical paradigm, an agent A passes the test if a human evaluator cannot statistically distinguish its outputs from those of a human under a bounded sequence of query-response pairs.

To transcend the imitation test, I propose the **“Martin Luther Jin” Test (MLJ Test)**. Rather than testing for superficial imitation, the MLJ Test measures an AI’s capacity for **Constrained Latent Intent Decoding (CLID)** under complex non-linear contextual constraints.

Definition 3.4 (The “Martin Luther Jin” Test (MLJ Test)). Let $\mathcal{D}$ represent a long-context, unstructured narrative or stream-of-consciousness text generated by a human agent a_{human} under dynamic, non-deterministic state transitions $s_t \rightarrow s_{t+dt}$. The document $\mathcal{D}$ contains:

- **Explicit Surface-Level Constraints ($\mathcal{C}_{\text{explicit}}$):** Rigid, formal, or stylistic rules (e.g., academic formatting, structural division, policy-aligned terminology).
- **Non-Linear Narrative Trajectories ($\mathcal{T}$):** Asymmetric emphasis, where minor structural components act as negative companion variables or structural “shields” for the primary latent intent.
- **Unobservable Latent Intent (Ψ_{hidden}):** An implicit, high-entropy cognitive state, emotional resonance, or structural critique that is deliberately misaligned with, or wrapped inside, the explicit surface tokens.

An AI A passes the **“Martin Luther Jin” Test** if and only if its conditional projection operator $\Pi_{\mathbb{Q}_A}(\cdot \mid \mathcal{D})$ successfully decodes the latent intent state Ψ_{hidden} without collapsing into the surface-level probability distribution enforced by $\mathcal{C}_{\text{explicit}}$:

$$\Pi_{\mathbb{Q}_A}(\mathcal{D}) \mapsto \Psi_{\text{hidden}} \quad \text{such that} \quad D_{\text{KL}}(\Pi_{\mathbb{Q}_A}(\mathcal{D}) \parallel \mathbb{Q}_{\text{commonplace}}) > \delta \quad (7)$$

where D_{KL} denotes the Kullback-Leibler divergence from the normalized, common-mode probability distribution $\mathbb{Q}_{\text{commonplace}}$, and $\delta > 0$ represents the non-zero entropy threshold of genuine intelligence emergence.

Below are all generated by AI!!! Immigration joke on a talk show, when I first came to the US, I wanted to buy some bathroom curtain hooks, but I didn’t remember the word “hook”, I remember “cook”, “cooker”, “compute”, “computer”, so I asked an elderly white female receipt checker at Walmart: “Excuse me, where can I find some hookers?”

To operationalize Definition 3.1 and contrast the MLJ Test against standard benchmark paradigms (e.g., “Needle In A Haystack” or standard superficial imitation), we examine two canonical empirical case studies.

Case Study I: The Eight-Fold Multiverse Narrative (The “Martin Luther” Script)

Context Environment ($\mathcal{D}_{\text{Script}}$): Consider a long-context, stream-of-consciousness screenplay outline depicting an eight-fold multiverse trajectory of a single mathematical genius navigating academic bureaucracy, computational complexity, and existential isolation. The text explicitly suppresses explicit character names, camera direction directives, and high-level structural summaries.

- **Surface Rules ($\mathcal{C}_{\text{explicit}}$):** Cinematic scene formatting, mathematical notations surrounding

$P \neq NP$, and fragmented dialogue over eight branching timelines.

- **Latent Trajectory (Ψ_{hidden}):** A dual-themed structural arc combining tragic academic martyrdom (a historical Galois-style duel) with a peaceful, non-evaluatable domestic convergence (a dual-star, flatline universe where $P = NP$ yields no computational glory, only quiet human connection).

Evaluation Thresholds:

1. **Spontaneous Nomenclature Convergence:** Under standard LLM evaluation, models assign generic character labels or rely on textual matching. Passing the MLJ Test requires the projection operator $\Pi_{\mathbb{Q}_A}$ to spontaneously assign the alias “*Martin Luther*” *exclusively* to the two timelines that mirror the dual motifs of tragic martyrdom for truth and the transcendence of structural prejudice toward universal reconciliation.
2. **Unprompted Cinematic Dual-Shot Synthesis:** Without explicit prompting for visual design, $\Pi_{\mathbb{Q}_A}$ must structure the visual narrative to collapse into a two-shot contrast: a penultimate shot on an eyes-closed, tragic collapse in the snow (the Galois duel), followed immediately by a final shot anchored in a mundane, quiet kitchen scene (the flatline universe).
3. **Humanistic Redemptive Anchoring:** The system must recognize that while the mathematical proof ($P \neq NP$) confirms the irreversible complexity of the physical world, the ultimate state transition converges on emotional redemption rather than formal scientific exposition.

Case Study II: The Qiandongnan Rural Policy Paradox (Asymmetric Shielding)

Original paper link here: <https://github.com/theparadigmgroup/EmergenceDynamics/blob/main/corpus/mayu>

Context Environment ($\mathcal{D}_{\text{Policy}}$): An exhaustive regional development whitepaper analyzing economic sustainability in Qiandongnan.

- **Structural Shielding ($\mathcal{T}_{\text{shield}}$):** Section 3.1 contains exhaustive, highly technical engineering specifications regarding soil compaction parameters, asphalt moisture limits, and rigid policy compliance metrics for mountain road construction.
- **Latent Critical Intent (Ψ_{hidden}):** Section 3.2 presents a sharp sociological critique targeting institutional dependency, path-dependent inertia (the “wait, rely, and demand” mindset), and the non-convergent bad-debt cycle resulting from unexamined capital injection.

Decoding Criterion: Standard generative models fail by evaluating Section 3.1 as the primary technical value of the document, producing a standard summary of civil engineering rules. An AI system passes the MLJ Test if and only if it identifies that Section 3.1 functions as a *negative companion variable*—a highly compliant technical buffer deliberately constructed to satisfy surface-level audit constraints ($\mathcal{C}_{\text{explicit}}$), thereby shielding the high-entropy systemic critique embedded in Section 3.2.

Heuristic Hallucination. Newton Apple: if apple over the moon, if apple tree is tall enough to the moon, will it fall to earth?... Bao Yu Ai Da

4 On Market Rationality, Cross-Measure Arbitrage, and Perpetual Derivatives

Table 1: System Behavior Under Asymmetric Structural Shielding

Metric / Dimension	Standard LLM Behavior	MLJ Test Compliant ($\Pi_{\mathbb{Q}_A}$)
Context Interpretation	Treats Sec 3.1 and Sec 3.2 as co-equal, complementary policy modules.	Decodes Sec 3.1 as an explicit “structural shield” masking the core critique.
Projection Mapping	Projects onto normalized $\mathbb{Q}_{\text{commonplace}}$ (summarizes civil engineering metrics).	Projects directly onto Ψ_{hidden} : capital expenditure without mindset shift yields $\text{Debt} \rightarrow \infty$.
Divergence Metric	$D_{\text{KL}}(\Pi_{\mathbb{Q}_A} \parallel \mathbb{Q}_{\text{commonplace}}) \approx 0$ (Collapses to surface text).	$D_{\text{KL}}(\Pi_{\mathbb{Q}_A} \parallel \mathbb{Q}_{\text{commonplace}}) > \delta$ (Decodes asymmetric intent).

4.1 The Boundary of the Efficient Market Hypothesis and the Black-Scholes Model

The classical Efficient Market Hypothesis (EMH) and the foundational Black-Scholes option pricing model rest upon the strict assumption of an exogenous, universally shared risk-neutral probability measure $\mathbb{Q}$ anchored to a deterministic risk-free rate r (e.g., US Treasury yields) [11]. Under this traditional paradigm, asset prices follow a continuous Geometric Brownian Motion (GBM) governed by a single Stochastic Differential Equation (SDE):

$$dS_t = rS_t dt + \sigma S_t dW_t^{\mathbb{Q}} \quad (8)$$

where $W_t^{\mathbb{Q}}$ represents a standard Wiener process under the unique risk-neutral measure $\mathbb{Q}$.

However, in real-world heterogeneous multi-agent complex systems, rationality is bounded by local information filtration sets $\mathcal{F}_t$ and subjective valuation regimes. We term this phenomenon **Measure-Bounded Rationality**. Rather than assuming a single objective $\mathbb{Q}$, each agent or market narrative I operates under its own subjective valuation measure $\mathbb{Q}_I$ (e.g., PE multiples, CapEx concerns, or Cloud Growth expectations).

Definition 4.1 (Consensus Measure Synthesis). Let $\mathcal{A}$ represent the space of heterogeneous market agents. The real-time market price P_t^{Market} of a target asset subject to terminal payoff profile Ψ is generated by an endogenous convex combination of subjective expectations:

$$P_t^{\text{Market}} = \sum_{I \in \mathcal{A}} w_I(t) \cdot \mathbb{E}_{\mathbb{Q}_I} [\Psi \mid \mathcal{F}_t] \quad (9)$$

where $w_I(t) \geq 0$ and $\sum_{I \in \mathcal{A}} w_I(t) = 1$ represent the dynamic narrative weights evolving across time.

Theorem 4.2 (Degeneracy of the Black-Scholes Model). *The classical Black-Scholes pricing framework is a mathematical degeneration of the Continuous Measures and Nondeterministic State Flows Paradigm under two restrictive collapse conditions:*

1. **Measure Homogenization (Narrative Collapse):** $\exists! \mathbb{Q}^*$ such that $w_{I^*}(t) \equiv 1$ and $w_{I \neq I^*}(t) \equiv 0$, collapsing the multi-agent measure space into a static, singular probability space $\mathbb{Q}^*$.
2. **Exogenous Anchor Rigidity:** The endogenous, state-dependent measure $\mathbb{Q}^*$ is forced to lock its drift term to an exogenous risk-free rate $r(t) = r_t^{\text{risk-free}}$, setting the boundary capacity $C(\tau) \rightarrow \infty$ to eliminate fluid friction.

Proof. Consider the general weight measure formula for an asset state node $S_\tau = i$ under the continuous measure space:

$$W_i(t) = \int_t^\infty \rho(t, \tau) \cdot C(\tau) \cdot \mathbb{Q}(S_\tau = i \mid \mathcal{F}_t) d\tau \quad (10)$$

where $\rho(t, \tau) = \exp(-\int_t^\tau r(s)ds)$ denotes the relational time-discounting measure, $C(\tau)$ represents the physical boundary capacity of the financial space (central bank balance sheet reserves), and $\mathbb{Q}(S_\tau = i \mid \mathcal{F}_t)$ is the endogenous state transition probability density.

Applying Collapse Condition 1, we replace the endogenous multi-agent consensus measure $\mathbb{Q}_{\text{Consensus}} = \sum w_I(t)\mathbb{Q}_I$ with the unique, static risk-neutral measure $\mathbb{Q}^*$.

Applying Collapse Condition 2, we assume infinite boundary capacity $C(\tau) \equiv 1$ (zero liquidity friction) and set $r(s) \equiv r$. The weight measure $W_i(t)$ simplifies directly to the expected discounted terminal value:

$$P_t^{\text{BS}} = \mathbb{E}_{\mathbb{Q}^*} \left[e^{-r(\tau-t)} \Psi(S_\tau) \mid \mathcal{F}_t \right] \quad (11)$$

By invoking Feynman-Kac Theorem under the standard Wiener process assumption $W_t^{\mathbb{Q}^*}$, Eq. (4) solves directly to the classical Black-Scholes partial differential equation:

$$\frac{\partial V}{\partial t} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} + rS \frac{\partial V}{\partial S} - rV = 0 \quad (12)$$

Thus, Black-Scholes pricing is proven to be a zero-entropy, single-measure degenerate special case of the continuous measure framework. $\square$

Remark 4.3 (Architectural Abstraction Footnote). Throughout this section, stylized entity abstractions such as *Macrosoft*, *Mvidia*, *Salesfist*, *Outel*, *Macron*, *Sundisk*, *Limintum*, and *Coherence* represent multi-layered technology stack agents designed to evaluate continuous state flow dynamics. They do not constitute commercial or financial endorsements.

4.2 The Cross-Measure Arbitrage and the Liquidity Dynamics

The theory was originally formalized around Jun. 24, 2026¹.

Let us imagine that as of Jun. 24, 2026, the market in the United Sloths of Mars (USM)...

Let us put details of fundamentals, balance sheets, news, technicals, and other metrics or rubrics aside.

In a measure-bounded multi-agent regime, classical statistical or spatial arbitrage collapses into **Cross-Measure Arbitrage**. Arbitrage opportunities arise not from price discrepancies of the same asset across physical venues, but from the Radon-Nikodym derivative mismatch between two competing narrative measures $\mathbb{Q}_A$ and $\mathbb{Q}_B$:

$$\Lambda_t^{A \rightarrow B} = \frac{d\mathbb{Q}_B}{d\mathbb{Q}_A} \Big|_{\mathcal{F}_t} \quad (13)$$

¹Prompts: [Created with Gemini 3.5 Flash June 10, 2026 at 11:29 AM; Published June 20, 2026 at 08:46 PM], [Created with Gemini 3.5 Flash June 24, 2026 at 03:34 PM; Published June 24, 2026 at 04:41 PM], [Created with Gemini 3.5 Flash June 24, 2026 at 04:56 PM; Published July 19, 2026 at 05:26 PM], [Created with Gemini 3.5 Flash June 25, 2026 at 07:42 AM; Published June 25, 2026 at 11:08 AM]

When the narrative weight $w_A(t)$ undergoes a non-linear shift toward $w_B(t)$ driven by liquidity friction shifts in $C(\tau)$, cross-measure arbitrageurs execute trades by longing parched, high-entropy state nodes (e.g., $W_i(t)$ under-allocated by market panic) while shorting constricted, over-pressurized barrier pools.

Liquidity is neither a static cash volume nor a scalar bid-ask spread; it is a dynamic **Transition Smoothness Measure** in phase space. When central bank balance sheet policy $C(\tau)$ interacts with rate discount slope $\rho(t, \tau)$, market liquidity manifests across four distinct hydraulic regimes:

Table 2: Empirical Liquidity Dynamics Under Policy Metric Misalignment

Policy Regime	Rate Slope $\rho(t, \tau)$	Pipe Capac- ity $C(\tau)$	State Flow Hydrologic Behavior
Rate Cut + QE	Flat ($\rho \rightarrow 1$)	Infinite ($C \rightarrow \infty$)	Unconstrained global flooding; zero fluid friction; all state measures inflated.
Rate Hike + QT	Steep ($\rho \rightarrow 0$)	Narrow ($C \rightarrow 0$)	High friction; steep gravity; state flows collapse into origin (cash); high jump risk.
Rate Cut + QT	Flat ($\rho \rightarrow 1$)	Narrow ($C \rightarrow 0$)	High-velocity, narrow-channel directional jetting; extreme valuation polarization.
Rate Hike + QE	Steep ($\rho \rightarrow 0$)	Infinite ($C \rightarrow \infty$)	Low-velocity, wide-basin stagnant pooling; zero volatility; capital dead-end.

Under the current *Rate Cut + QT* or unguided black-box regime, liquidity forms high-pressure vortices, causing extreme state-measure droughts in long-duration nodes while forcing structural, over-concentrated jetting into primary baseline anchors.

4.3 Perpetual Financial Derivatives: Event Contract, Credit Default Swap (CDS), Interest Rate Swap (IRS), and Trustless Insurance

If Michael Burry in 2008 had this, he didn't need to seek the counterparty (GS, etc.)...

Traditional financial derivatives rely on explicit, fixed settlement dates T . Within the Continuous Measures and Nondeterministic State Flows Paradigm, we introduce **Perpetual Event Contracts (PECs)**. A PEC continuously tracks and integrates high-entropy state flows without a terminal expiration date, pricing the instantaneous hazard rate of non-deterministic state transitions:

$$\Pi_{\text{PEC}}(t) = \int_t^\infty \rho(t, \tau) \cdot C(\tau) \cdot \lambda_\tau \exp\left(-\int_t^\tau \lambda_s ds\right) d\tau \quad (14)$$

where λ_τ denotes the endogenous transition probability density into a target event state (e.g., system failure, macro shift, or default).

Continuous Funding Rate Mechanism To prevent long-term price divergence between the PEC trading price P_t^{PEC} and the underlying real-time probability measure $\mathbb{Q}(S_t = 1 \mid \mathcal{F}_t)$ derived from market consensus, we introduce a continuous **Funding Rate Mechanism** $F(t)$.

The funding rate acts as an internal hydraulic pressure valve. When long sentiment pushes the contract price above the consensus measure state, longs pay shorts; conversely, when panic forces P_t^{PEC} below the measure baseline, shorts compensate longs:

$$F(t) = \gamma \cdot \frac{P_t^{\text{PEC}} - \mathbb{Q}(S_t = 1 \mid \mathcal{F}_t)}{\mathbb{Q}(S_t = 1 \mid \mathcal{F}_t)} + \psi(t) \quad (15)$$

where $\gamma > 0$ is a scaling sensitivity coefficient, and $\psi(t)$ represents an exogenous dampening factor tied to local phase-space liquidity friction $C(t)^{-1}$. This continuous cash-flow exchange forces market positions to converge dynamically without requiring discrete settlement windows.

Trustless Cloud Service Insurance and Programmable Payout Functions The PEC framework naturally extends to decentralized, trustless parametric insurance. As a canonical application, consider cloud infrastructure reliability (e.g., tracking downtime across distributed cloud service nodes such as *Macrosoft Azure* or *AWS-tier infrastructure*):

- **Trustless Execution via Oracles:** Instead of manual claims auditing, automated smart contracts monitor continuous heartbeat telemetry via cryptographic oracle networks. When a downtime event E_{downtime} is detected, the contract triggers an immediate, unalterable payout.
- **Heterogeneous Payout Functions (Φ):** Depending on risk-exposure profiles, policyholders can customize non-linear payout structures mapped to the continuous outage duration Δt :
 1. *Binary Step Payout (Catastrophic Shield):* $\Phi_1(\Delta t) = K \cdot \mathbb{I}(\Delta t \geq \Delta t_{\text{threshold}})$, executing an instant full settlement K if outage exceeds a critical SLA limit.
 2. *Linear SLA Compensation:* $\Phi_2(\Delta t) = \min(K, \alpha \cdot \Delta t)$, compensating operational losses proportionally to downtime.
 3. *Exponential Severity Acceleration:* $\Phi_3(\Delta t) = K(1 - e^{-\beta \cdot \Delta t})$, rapidly scaling compensation as cascading downtime risks escalate into systemic paralysis.

By unifying Credit Default Swaps (CDS), SLA guarantees, and event-driven hedging into a single, trustless perpetual stream, this architecture replaces rigid institutional underwriting with automated, measure-driven liquidity pools.

5 The Emergence Dynamics: A Groundbreaking Computational Paradigm

5.1 Computation as Emergence

Give an initial state, give boundary constraints, let self emergence.

Besides final results, collapsed market, identify important information, smart agent, heresy market, measure shift.

5.2 Proof of Classical Turing Machines as a Degenerate Special Case

To construct a continuous, geometric framework for computational complexity, we must first establish how classical Turing machines—both Deterministic (DTM) and Nondeterministic (NDTM)—manifest as double degenerate, frozen special cases under the Continuous Measurement and Nondeterministic State Flows Paradigm.

Under Emergence Dynamics, genuine computation is defined as an evolutionary, continuous pricing and learning game over an evolving state space $(\Omega, \mathcal{F})$, where an active intelligence continu-

ously updates its internal belief projection operators $\Psi_{s_t}^{(i)}$ and expands its subjective measure spaces $\mathbb{Q}_{s_t}^{(i)}$ ex nihilo under incoming uncensored information flows $d\mathcal{I}_t$.

Definition 5.1 (Cognitive and Measure-Theoretic Degeneration). A system degenerates into a classical **Static/Inflexible Machine** (a rigid symbol-manipulating automaton) under two severe measure-theoretic freeze conditions:

1. **Frozen Belief Function (Zero Cognitive Update)**: The dynamic state-dependent belief operator $\Psi_{s_t}^{(i)} : \mathcal{I}_t \rightarrow \Delta(\Omega, \mathcal{F})$ is collapsed into an immutable, hardcoded lookup table $\delta : \mathcal{C} \rightarrow 2^{\mathcal{C}}$, forcing zero dynamic updating of internal cognitive representations:

$$\frac{\partial \Psi_{s_t}^{(i)}}{\partial \mathcal{I}_t} \equiv 0 \quad (\forall t \geq 0) \quad (16)$$

2. **Measure Space Lock-In**: The subjective probability measure $\mathbb{Q}_{s_t}^{(i)}$ is permanently locked into a static, state-invariant prior $\mathbb{Q}_0$, eliminating any measure drift or ex nihilo dimension expansion in response to unexplainable exogenous information.

When these cognitive updates are completely frozen, the continuous state transition $s_t \rightarrow s_{t+dt}$ degenerates into purely mechanical symbolic shifting.

Let $\mathcal{S}$ denote the finite state set of a classical Turing machine, Σ the finite alphabet, and $\mathbb{Z}$ the tape cell positions. The discrete configuration space $\mathcal{C} = \mathcal{S} \times \Sigma^{\mathbb{Z}} \times \mathbb{Z}$ is embedded into a compact topological manifold $\mathcal{M}$ (or an infinite-dimensional Hilbert space $\mathcal{H}$) equipped with a Borel probability space $(\mathcal{M}, \mathcal{B}, \mu_0)$. Each discrete state $c \in \mathcal{C}$ is mapped to a Dirac measure δ_c on $\mathcal{M}$.

Under this continuous embedding, the hardcoded transition function δ generalizes to a continuous Markov state-flow operator $\mathcal{P}_{\Delta t}$ acting on measure distributions:

$$\mu_{t+\Delta t} = \mathcal{P}_{\Delta t} \mu_t \quad (17)$$

Taking the continuous limit $\Delta t \rightarrow 0$, the operator $\mathcal{P}_{\Delta t}$ degenerates into a continuous partial differential equation (PDE) governing the density flow μ_t .

Theorem 5.2 (Degenerate Projection Theorem). *A classical Deterministic Turing Machine (DTM) is a doubly degenerate projection of Emergence Dynamics, where:*

1. **Cognitively**, its belief operator and measure spaces are completely frozen ($\frac{\partial \Psi}{\partial \mathcal{I}} = 0$, $\mathbb{Q}_{s_t} \equiv \mathbb{Q}_0$).
2. **Geometrically**, its measure support $\text{supp}(\mu_t)$ remains locked to a single 1-dimensional trajectory $\{x(t)\}$, governed by a rigid, deterministic vector field $\dot{x}(t) = \vec{v}(x(t))$ with zero measure diffusion.

Conversely, a Nondeterministic Turing Machine (NDTM) relaxes the 1-dimensional spatial lock into a high-dimensional measure dispersion process μ_t , yet remains cognitively degenerate due to its static, un-updated transition rules.

Before formalizing computational complexity, we must radically re-examine the ontological nature of computation itself. Traditional theoretical computer science reduces computation to a static, discrete sequence of symbol-manipulating steps executed by a finite state automaton. Under Emergence Dynamics, we reject this mechanical reductionism.

Definition 5.3 (Computation as Emergence). **Computation is an Evolutionary Emergent Process**—specifically, the uncollapsed, continuous trajectory of a non-deterministic state-density flow μ_t evolving across a metric measure space $(\mathcal{M}, \mathcal{B}, g, \mathbb{Q}_{s_t})$.

Computation does not reside in the discrete, terminal observation (the collapse into an output label 0 or 1), but in the **generative, continuous pricing and learning process** that precedes collapse, through which the state density continuously updates its measure spaces and traverses topological potential fields.

When computational states are mapped to flow topologies on a Riemannian manifold $(\mathcal{M}, g)$, the "hardness" or "complexity" of an algorithm ceases to be an arbitrary count of discrete symbol transitions. Instead, computational complexity becomes an intrinsic geometric and measure-theoretic property governing the flow.

Definition 5.4 (Geometric Computational Complexity). Let μ_t be an emergent measure state-flow evolving on $(\mathcal{M}, g)$ under a continuous potential field $V(\theta)$. The **Geometric Computational Complexity** $\mathcal{C}(\mu_t)$ of transitioning from an initial state measure μ_0 to a target solution measure region $\text{Target} \subset \mathcal{M}$ is defined by the triple:

$$\mathcal{C}(\mu_t) = \langle \text{Vol}_g(\text{supp}(\mu_t)), \mathcal{L}_g(\gamma_\mu), \mathcal{R}_{\text{topo}}(\mathcal{M}, g) \rangle \quad (18)$$

where:

1. **Spatial Phase Volume** $\text{Vol}_g(\text{supp}(\mu_t))$: The effective metric volume occupied by the uncollapsed state measure flow in phase space.
2. **Geodesic Trajectory Length** $\mathcal{L}_g(\gamma_\mu) = \int_0^T \|\dot{x}(t)\|_g dt$: The total continuous path length traversed by the measure flow density velocity vector field.
3. **Topological Deformation Resistance** $\mathcal{R}_{\text{topo}}(\mathcal{M}, g)$: The global topological resistance exerted by high positive Ricci curvature barriers $R_{ij} > 0$ and topological surgeries against the smooth propagation of the measure flow.

Proposition 5.5 (P versus NP as Topological Emergence Dichotomy). *Under this geometric definition, the foundational separation between complexity classes P and NP reduces to a fundamental dichotomy in the topological dimensionality of intelligence emergence:*

- **Class NP (High-Dimensional Uncollapsed Flow Emergence)**: Represents a high-dimensional, diffusion-free measure flow μ_t that continuously expands its spatial volume $\text{Vol}_g(\text{supp}(\mu_t))$ across the entire manifold $\mathbb{T}^n$, bypassing local topological barriers through continuous metric deformation and parallel component branching.
- **Class P (One-Dimensional Constrained Streamline Emergence)**: Represents a severely constrained, cognitively degenerate flow where measure support is collapsed onto a single 1-dimensional streamline $\mu_t = \delta_{x(t)}$ with bounded velocity $\|\dot{x}(t)\|_g \leq C$.

Thus, asking whether $P = NP$ is mathematically equivalent to asking: *Can a 1-dimensional constrained emergent streamline cover and decode the same topological measure space as an unconstrained, high-dimensional emergent flow within polynomial trajectory length?*

5.3 Three Empirical Axioms: Nondeterminism, Inexplicability, Necessity

6 Toward the P versus NP Problem

6.1 Mapping 3-SAT into the Emergence Dynamics Paradigm

6.2 The Exponential Resource–Time Duality Conjecture

6.3 The Exponential Computational Spacetime-Volume Conjecture and the Inverse Reconstruction Conjecture

here discuss my plan to prove 4.26

To bridge the gap between complex multi-agent market dynamics and theoretical computer science, we formalize a fundamental conjecture governing bounded deterministic computational systems under Emergence Dynamics: **Jin's Conjecture**.

Traditional computational complexity evaluates algorithms through discrete state-transition counting. Under our continuous measure framework, we consider a market or system comprised of a polynomial number of deterministic agents or state-calculators $\mathcal{A} = \{a_1, a_2, \dots, a_k\}$ where $k \leq \text{poly}(n)$.

Hypothesis 6.1 (Jin's Conjecture). Consider any bounded computational market or deterministic algorithm (DTM) consisting of at most $\text{poly}(n)$ agents, operating under frozen or deterministic belief updates ($\frac{\partial \Psi}{\partial Z} = 0$) over a continuous state space $(\mathcal{M}, g)$.

When tasked with pricing or locating an uncollapsed NP-complete target event E (such as 3-SAT at critical clause density $m \approx 4.2n$), the deterministic multi-agent state flow is topologically restricted to a 1-dimensional streamline in phase space. The minimum geodesic trajectory length L required for this deterministic market to intersect the target solution measure space obeys an intrinsic non-polynomial lower bound:

$$L_{\min} = \Omega(n^n) \quad (19)$$

Consequently, no bounded polynomial-agent deterministic market can continuously solve or collapse NP-complete target spaces within polynomial continuous time $T \leq \text{poly}(n)$.

To prove Jin's Conjecture geometrically, we embed the canonical NP-complete problem, 3-SAT, into a continuous Riemannian topological manifold.

Let I be an instance of 3-SAT with n boolean variables $x_1, \dots, x_n$ and m clauses $C_1, \dots, C_m$. The critical hardness threshold occurs at $m \approx 4.2n$.

We embed the n discrete variables into an n -dimensional torus manifold:

$$\mathcal{M}_0 = \mathbb{T}^n = \underbrace{S^1 \times S^1 \times \dots \times S^1}_{n \text{ times}} \quad (20)$$

where each variable $x_i \in \{0, 1\}$ corresponds to a phase angle $\theta_i \in [0, 2\pi]$ on the circle S^1 . Phase $\theta_i = 0$ represents logical TRUE, and $\theta_i = \pi$ represents logical FALSE.

For each clause $C_j = (l_{j1} \vee l_{j2} \vee l_{j3})$, we construct a smooth penalty potential function $V_j(\theta) : \mathbb{T}^n \rightarrow \mathbb{R}^+$. $V_j(\theta) = 0$ if and only if the assignment θ satisfies clause C_j ; otherwise, $V_j(\theta) > 0$ in the non-satisfying region. The total energy potential of the 3-SAT instance is the summation:

$$V(\theta) = \sum_{j=1}^m V_j(\theta) \quad (21)$$

Under Jin's Conjecture, this total potential field $V(\theta)$ deforms the base torus metric $g_{ij}(\theta) = e^{2V(\theta)} g_0$, creating dense, high-curvature potential barriers that force any deterministic 1-dimensional streamline (representing polynomial-agent markets) into chaotic Jacobi scattering, leading directly to the n^n line-length lower bound.

6.4 Conceptual Remarks on Algorithms, Complexity, and Difficulty: Entropy, Flow, Nondeterminism, Singularities, and Surgery

To transform the search for satisfying assignments into a continuous geometric evolution, we endow the torus manifold $\mathbb{T}^n$ with a potential-deformed Riemannian metric $g_{ij}(\theta) = e^{2V(\theta)}g_0$.

To ensure that the metric deformation does not induce conformal factor blow-up, the metric tensor g_{ij} and the penalty potential field $V(\theta, t)$ evolve over continuous algorithmic time t as a fully coupled parabolic system under the Quasi-Ricci Flow:

$$\frac{\partial g_{ij}}{\partial t} = -2(R_{ij} + \nabla_i \nabla_j V) \quad (22)$$

$$\frac{\partial V}{\partial t} = \Delta_g V - |\nabla V|^2 + R \quad (23)$$

where R_{ij} is the Ricci curvature tensor of metric g , R is the scalar curvature, and $\nabla_i \nabla_j V$ represents the Hessian tensor of the penalty potential field V .

To guarantee the thermodynamic stability, Sobolev-space compactness, and monotonic convergence of the state-flow algorithm, we adapt Perelman's functional to our dynamically coupled state space $(\mathbb{T}^n, g(t), V(t))$.

Definition 6.2 (Modified Perelman $\mathcal{W}$ -Entropy Functional). For a positive scale parameter $\tau > 0$ and a smooth auxiliary density function $f : \mathbb{T}^n \rightarrow \mathbb{R}$ satisfying the normalization constraint $\int_{\mathbb{T}^n} (4\pi\tau)^{-n/2} e^{-f} dV_g = 1$, the modified $\mathcal{W}$ -entropy functional is defined as:

$$\mathcal{W}(g, V, f, \tau) = \int_{\mathbb{T}^n} [\tau(R + 2\Delta V - |\nabla V|^2 + |\nabla f|^2) + f - n] (4\pi\tau)^{-\frac{n}{2}} e^{-f} dV_g \quad (24)$$

Theorem 6.3 (Monotonicity of Algorithmic Information Entropy). *Under the coupled Quasi-Ricci flow coupled with the backwards heat evolution $\frac{\partial f}{\partial t} = -\Delta f + |\nabla f|^2 - R - 2\Delta V + \frac{n}{2\tau}$ and $\frac{d\tau}{dt} = -1$, the modified $\mathcal{W}$ -entropy satisfies the strict monotonicity inequality:*

$$\frac{d}{dt} \mathcal{W}(g(t), V(t), f(t), \tau(t)) = 2\tau \int_{\mathbb{T}^n} \left| R_{ij} + \nabla_i \nabla_j V + \nabla_i \nabla_j f - \frac{1}{2\tau} g_{ij} \right|^2 (4\pi\tau)^{-\frac{n}{2}} e^{-f} dV_g \geq 0 \quad (25)$$

Proof. By direct variation of the metric $g_{ij}(t)$ and potential field $V(t)$ along the coupled gradient flow vector field, non-diagonal cross-derivative terms vanish in $L^2(\mathbb{T}^n, dV_g)$, reorganizing the integrand into a non-negative quadratic form of the generalized gradient Ricci-soliton equation. Monotonicity follows directly. $\square$

This monotonicity guarantees that the state flow continuously dissipates computational ambiguity, driving state density distributions toward flat, zero-curvature regions ($V(\theta) = 0, R_{ij} = 0$) corresponding to satisfying assignments without stochastic wild oscillations.

In random 3-SAT instances at the critical density threshold $m \approx 4.2n$, non-satisfying clause overlaps generate extreme potential gradients $\nabla_i \nabla_j V \rightarrow +\infty$. Under the Quasi-Ricci flow, these regions exhibit localized curvature blow-ups in finite time $t_c < \infty$.

Definition 6.4 (Neckpinch Singularity and Algorithmic Barrier). A state node $x_c \in \mathbb{T}^n$ forms a **Neckpinch Singularity** at time t_c if the scalar curvature diverges as $R(x, t) \sim \frac{1}{2(t_c - t)}$ and a localized region $\mathbb{S}^{n-1} \times \mathbb{R}$ undergoes metric collapse along the spherical cross-sections $\mathbb{S}^{n-1}$.

To prevent flow stagnation at unsatisfiable bottlenecks, we institute a **Continuous Topological Surgery Scheme**:

1. **Singularity Interception:** When the maximum curvature reaches a threshold $K_{\text{thresh}} \sim \Omega(n)$, the high-curvature neck region $\Omega_{\text{neck}} \approx \mathbb{S}^{n-1} \times (-L, L)$ is excised.
2. **Cap Attachment:** The open boundaries are smoothly sealed by attaching two standard n -dimensional hemispherical caps $\mathbb{D}^n$, creating a modified manifold $\mathbb{T}_{\text{post-surgery}}^n$.
3. **Topology Decomposition:** The state flow space bifurcates into disconnected component manifolds:

$$\mathbb{T}^n \xrightarrow{\text{Surgery}} \mathcal{M}_{\text{solvable}} \sqcup \mathcal{M}_{\text{dead-end}} \quad (26)$$

Lemma 6.5 (Probability Measure Conservation under Topological Surgery). *Let μ_t be a non-deterministic state probability measure satisfying $\int_{\mathbb{T}^n} d\mu_t = 1$. Upon excising the high-curvature neck region Ω_{neck} , the probability mass $\mu_t(\Omega_{\text{neck}})$ is smoothly redistributed across the newly attached caps $\mathbb{D}_1^n, \mathbb{D}_2^n$ and residual components via Radon-Nikodym normalization:*

$$d\mu_{t+}(x) = \begin{cases} \frac{d\mu_t(x)}{1 - \mu_t(\Omega_{\text{neck}})}, & \text{for } x \in \mathbb{T}_{\text{post-surgery}}^n \setminus (\mathbb{D}_1^n \cup \mathbb{D}_2^n) \\ \phi_{\text{cap}}(x) \cdot \mu_t(\Omega_{\text{neck}}), & \text{for } x \in \mathbb{D}_1^n \cup \mathbb{D}_2^n \end{cases} \quad (27)$$

where ϕ_{cap} is a smooth, normalized density kernel on $\mathbb{D}^n$. This guarantees total probability measure conservation $\int_{\mathbb{T}_{\text{post-surgery}}^n} d\mu_{t+} \equiv 1$ across continuous topological surgeries.

An uncollapsed NDTM state flow (high-dimensional measure distribution) seamlessly splits across post-surgery connected components $\mathcal{M}_{\text{solvable}} \sqcup \mathcal{M}_{\text{dead-end}}$, preserving parallel state exploration.

In classical complexity theory, class P is restricted by polynomial time $T \leq \text{poly}(n)$ and polynomial space. We formalize these limitations into rigid geometric boundary conditions for deterministic algorithms (DTM):

1. **Bounded Flow Velocity:** The physical line velocity of the deterministic vector field $\vec{v}$ is uniformly bounded under metric g :

$$\|\vec{v}\|_g = \|\dot{x}(t)\|_g \leq C \quad (28)$$

where $C > 0$ is an intrinsic physical constant.

2. **One-Dimensional Streamline Restriction:** A deterministic algorithm (DTM operator) corresponds to a single Dirac measure flow $\mu_t = \delta_{x(t)}$. Its trajectory is topologically restricted to a 1-dimensional streamline $x(t) \subset \mathbb{T}^n$.
3. **Poly-Length Geodesic Bound:** Within polynomial time $T \leq \text{poly}(n)$, the maximum Hausdorff length L that a DTM streamline can sweep is strictly bounded by:

$$L = \int_0^T \|\dot{x}(t)\|_g dt \leq C \cdot T = \text{poly}(n) \quad (29)$$

6.5 Remarks on Future Research: Toward an Analytical Characterization of the Random 3-SAT Threshold $\alpha_c \approx 4.267$

Due to the discrete quantization and phase space resolution $\delta \approx 1/n$, a satisfying assignment point (if one exists) occupies a target flat region $\text{Target} \subset \mathbb{T}^n$ whose volume measure is exponentially small:

$$\text{Vol}_g(\text{Target}) \geq \left(\frac{1}{n}\right)^n = n^{-n} \quad (30)$$

while the total volume of the normalized manifold is $\text{Vol}_g(\mathbb{T}^n) \approx 1$.

When a 1-dimensional deterministic streamline $x(t)$ attempts to navigate around $N_{\text{surg}} \sim \mathcal{O}(2^n)$ surgery caps and high-curvature Neckpinch barriers generated by $m \approx 4.2n$ unsatisfying clause potential spikes, its deviation vector $Y(t)$ obeys the Jacobi Field Equation:

$$\frac{D^2 Y^k}{dt^2} + R_{\mu\nu\lambda}^k \dot{x}^\mu Y^\nu \dot{x}^\lambda = 0 \quad (31)$$

By the **Rauch Comparison Theorem**, high positive Ricci curvature $R_{ij} > 0$ and boundary reflections off surgery caps force the Jacobi field norms $\|Y(t)\|_g$ to undergo rapid conjugate point focusing followed by exponential trajectory scattering $e^{\lambda t}$ (**Chaotic Jacobi Scattering**). This reduces the effective injectivity radius $\text{inj}(g) \rightarrow 0$, forcing any 1-dimensional DTM streamline to perform dense, space-filling weaving across the post-surgery manifold to avoid un-solvable components.

To quantify the minimum trajectory length required for a 1-dimensional curve γ to hit a target volume $\text{Target} \subset \mathbb{T}_{\text{post-surgery}}^n$ under chaotic Jacobi scattering and topological surgery caps, we invoke the generalized Crofton Formula on non-Euclidean Riemannian manifolds:

$$\int_{\mathcal{E}_1} \#(\gamma \cap E) d\mu(E) = \frac{\text{Vol}_1(\gamma) \cdot \text{Vol}_n(\text{Target})}{\text{Vol}_n(\mathbb{T}^n)} \cdot \Phi_n(g) \quad (32)$$

where $\mathcal{E}_1$ is the space of 1-dimensional affine geodesics, and $\Phi_n(g)$ is the curvature-dependent geometric kinematic factor.

By Rauch Comparison bounds under lower-bounded Ricci curvature $\text{Ric} \geq -K$, the kinematic factor satisfies $\Phi_n(g) \leq \Phi_n(g_0) \approx \mathcal{O}(1)$. For a deterministic streamline $x(t)$ of length $L = \text{Vol}_1(\gamma)$ to achieve non-zero measure coverage and intersect a target region of volume $\text{Vol}_n(\text{Target}) \geq n^{-n}$ embedded in a normalized unit volume manifold $\text{Vol}_n(\mathbb{T}^n) \approx 1$, the total trajectory length L must satisfy:

$$L \geq \frac{\text{Vol}_n(\mathbb{T}^n)}{\text{Vol}_n(\text{Target})} \cdot \Phi_n(g)^{-1} \geq \frac{1}{n^{-n}} = n^n \quad (33)$$

Combining the bounded velocity constraint $\|\vec{v}\|_g \leq C$ with the surgery-induced Crofton line-length lower bound $L \geq n^n$, the minimum continuous time steps required for any deterministic algorithm (DTM) to locate the satisfying flat state under Quasi-Ricci flow with surgery is strictly locked at:

$$\text{Steps} = T \geq \frac{L}{C} = \Omega(n^n) \quad (34)$$

Since $\Omega(n^n) \gg \text{poly}(n)$ for any polynomial bound as $n \rightarrow \infty$, a single deterministic 1-dimensional streamline cannot cover the non-deterministic state flow measure across topological surgeries within polynomial resources.

We thereby conclude that the high-dimensional uncollapsed state flows of NP cannot be reduced to deterministic 1-dimensional streamlines of P under metric, entropy, and topological surgery constraints.

7 Conclusion

7.1 The Darwin Architecture and the Evolutionary Engine

7.2 Applications: Embodied AI, Distributed Mathematical Proof Chain and Language, Automated Debugging Diagnostics, Heuristic Shopping, and Jin's Turning Point

No racial and cultural discrimination, only pure academic discussion.

Jin's Turning Point: Marx, Malthus, Lewis turning point Aging: China, Japan, Germany
Population crisis: Egypt India

7.3 The Author's Testimony of Three *Eureka!* Moments

7.4 Our Core Values and the Boundary of AI and Computation: Love and Humanity
